RIGGING A LOAD

HOW TO SET UP A RIGGING

This section applies to rigging in general, regardless if it is for a crane, beam truss, or lifting a load with a piece of equipment. The following principles always apply to ensure the load is rigged safely.

Rigging is used to connect loads to the hook of a crane. Slings, shackles, eyebolts, and other rigging hardware are used to make loads safer than they would be if rigging was not used.

Rigging is exact ought to an simple as attaching a single sling to an object with a shackle and a hook or can be very complex. The weight of the object, size, shape, and center of gravity will have an effect on the rigging hardware that is used.

QUALIFIED RIGGERS

- The rigger shall be qualified in the fundamentals of rigging. This qualification shall include training on at least the following topics: the basics of the equipment, recognition and inspection of slings, the rigging hitches, selection of hardware, application of slings, and load control basics, as applicable to the equipment. The rigger shall be qualified through a third party, or by the employer, or by licensing, or a Company-qualified evaluator. For employer owners the employer shall be qualified by a third party. Documentation of a rigger's record of such successful training and evaluation shall be kept on file by the employer.
- All rigging shall be inspected each shift before use.
- The rigger who rigs the load shall inspect the load once the load is lifted a few inches off the ground to ensure the load and there are no issues arising there.
- Taglines shall be used to control loads. The qualified rigger shall determine if tagging is necessary. Where tagging is used, qualified rigger determines the number of tag lines required. It is important to review each load and the length of the tagline to ensure it is not too long or too short. Tagline should be long enough to allow the rigger, or the hand to handle the load from the material. If lines are sharp edges, corner softeners can be used as directed by the manufacturer to protect the rope. The rope can be utilized like a resistant to cutting.
- Prior to the commencement of any lift, rigging shall be inspected for defects. Rigging hardware that is damaged, shop-made, Group Ives, or, except, shall be used to insure quickly "hard" hardware is prohibited.
- When not in use, rigging and rigging hardware shall be stored in a manner to prevent damage.

GENERAL REQUIREMENTS

- All rigging hardware shall comply with the Safe Working Load Limit (SWLL) or Working Load Limit (WLL) specified on the rigging. Rigging devices clearly display the WLL for the device. However, some hardware, such as chain and wire rope, may require calculations for the capacity. These capacities can be found in the manufacturers load rating charts. These capacities can be found in the manufacturers load rating charts. Rigging hardware shall be used in accordance with the manufacturer's recommendations and limitations. It is important to review each load and the length of the tagline to ensure it is not too long or too short. Tagline should be long enough to allow the rigger, or the hand to handle the load from the material. If lines are sharp edges, corner softeners can be used as directed by the manufacturer to protect the rope. The rope can be utilized like a resistant to cutting.
- In general, rigging is required to have a design factor of 5:1. This means that the ultimate breaking strength of the device is five times greater than the rated load. Rigging that does not meet this design factor rigging can be overloaded. Never Exceed the WLL of rigging hardware.

NEVER EXCEED "WLL" OF RIGGING DEVICES

NEVER OVERLOAD

Wear rigging hardware is designed so that there is a warning before a failure occurs. The hardware is designed to stretch out of shape before it breaks. Hooks will open up, and shackle pins will deform. If a hardware item is seen overloaded, do not use hardware.

Slings - all rules and regulations regarding slings used to rigs can be found under ANSI/ASME B30.9

Synthetic - all rules and regulations regarding hardware can be found under ANSI/ASME B30.9 for Rigging Hardware or B30.10 for Hooks.

PURCHASING RIGGING

When purchasing rigging, it is necessary to do business with a reputable supply source. The Company has committed to only using rigging made within the USA or Canada.

Some rigging such as wire rope slings can be difficult to verify the WLL. The rigging can be the most common because of their flexibility, durability, abrasion resistance, and ability to conform to the shape of a load. The wire rope slings are also the most expensive, so there is consideration when selecting a sling. Cost and durability alone make the wire rope sling the most economical sling available.

Storage

Wire rope slings when not in use should be stored in a location that will protect them from being damaged by equipment, exposure to heat, corroding water, or rust. It is recommended that these slings be stored in a dry location. Slings should not be stored where they will be exposed to acid fumes or other corrosive vapors because acid and vapor can cause severe damage to the sling that can cause injuries when unrolled.

Inspection

ANSI/ASME B30.9 requires slings to be inspected as follows:

- Initial inspection - prior to use on all new slings
- Frequent - Before each day use
- Periodic - Not to exceed one year. Should be documented.

All items of these inspections are essentially the same. The only conditions below are noted during any of these inspections, the sling must be removed from service.

If a nonrepairable condition exists, the sling should be destroyed by cutting the eyes of the sling making it impossible for the sling to be used.

If the sling is in good condition and only the capacity tag is missing or illegible, the sling can be tagged for the manufacturer and destroyed or returned.

Since most wire rope slings don't have an identifying number, documentation of the periodic inspection is difficult. The use of colored tape can serve as documentation of the inspection.

Some replacement criteria for wire rope slings include:

- 10 randomly distributed broken wires in one rope lay
- 5 broken wires in one lay in one rope lay
- Kinking
- Birdcaging
- Crushing
- Damage in rope structure
- Evidence of heat damage
- Corrosion
- Missing or illegible sling identification

Do not confuse the replacement criteria for wire rope slings with the replacement criteria for running ropes on cranes. Its eliminate, inclination criteria are not applicable to wire rope slings.

Synthetic Slings

Synthetic web slings come in many different forms. These slings are popular because of their lightweight, high strength characteristics. Compared to wire rope slings, synthetic and nylon slings are more expensive and are not as durable as wire rope slings. Another characteristic is that stored energy is not an issue with synthetic slings.

Synthetics or nylon slings are the other hand have characteristics that are not as desirable. They are not as resistant to abrasion and will fail if the load is moved over the sharp edges. Burning and cutting are other characteristics. These slings are very susceptible to damage from acid or caustic materials. Nylon slings are not affected by mildew or ultraviolet rays like the rest. They are also affected by heat and will need in step-by-step rigging.

Synthetic or nylon slings can be used to grip loads of many contours. It is also important that the load contacts the entire bearing surface of sling. This surface can either cut or burn the sling and cause the lose to fall. It is always a good practice to use "softeners" when using synthetics or nylon slings.

Web Slings

Web slings offer good protection for machine parts, are noncorrosive (when dry), lightweight and flexible. The sling is usually made of nylon or polyesters, depending on the chemicals involved.

The different materials have their own characteristics for resistance to damage from various liquids. For instance, polyester can be used with acids and not affected by them, but nylon cannot be used where it is temperatures up to 200 degrees F.

Web slings are made by sewing layers of nylon webbing together through many rows of stitching. Only one size is used for a specific for several reasons. Be aware that double ply slings may not have double the capacity of a single ply sling.

Acceptable Types of Web Slings

Unacceptable Types of Web Sling Sewn Shoulders

Acceptable Types of Web Sling Sewn Shoulders

Do not use hardware that is not specifically designed to be used with slings. Hardware must be of sufficient strength to not affect the rated capacity of the sling. The hardware must be of such design and proper size that it will be properly seated for supporting and pressing.

Some replacement criteria for nylon web sling include:

- Holes, tears, cuts, abrasion wear, or snags
- Acid or caustic burns
- Melting or charring of any part of the sling
- Kinking
- Broken or worn stitching in load bearing yarns
- Discoloration and stiff or brittle areas may mean chemical or ultraviolet damage has occurred
- Fittings that are bent, twisted, gouged, cracked, hardened, or broken
- Missing or illegible sling identification

Some webbing manufacturers may include red threads within the webbing to indicate when the sling is worn beyond use. When the red threads are exposed, the sling should be removed from service. If the manufacturer does not use red threads, the sling must be removed from service even though this is not part of the ANSI/ASME requirements for replacement. This is not to say that you should use a sling that is not on the edge of the red threads are exposed.

Synthetic Endless Round Slings

Endless round slings are made up of the most forgiving of the lightweight slings. These slings are constructed of load-carrying fibers covered with a tough non-load carrying cover. The load carrying fibers are made of many continuous filaments of high tenacity polyester yarn. The number of fibers and the size of the yarn is dependent on the capacity desired. The cover is sewn together to completely encompass the yarn. A second sewn is applied to the sling to protect the inner cover or sleeve.

These slings can be made in any length desired. Some manufacturers making them an attractive choice where large slings are needed. Endless round slings are rated at 100% efficiency in all hitches. Since there are so many manufacturers making these slings, the color of the cover cannot be relied upon to determine the capacity.

Always refer to the individual sling's WLL capacity tag to determine capacity.

Synthetic Endless Round Slings

Slings

With all synthetic type slings, sewage practices are key to the longevity of the sling. Since these slings are more fragile and more expensive than wire rope slings, it is important that they are kept in a dry location out of sunlight to protect the slings from the elements.

Inspection

Synthetic web slings shall be used per the ANSI/ASME B30.9 Criteria the same as wire rope slings for frequency of inspection.

- Initial Inspection - upon purchase and before use
- Frequent - Before each day use
- Periodic - Not to exceed one year. Should be documented.

Some replacement criteria for synthetic round slings include:

- Holes, burn, cuts, abrasion wear, or snags that expose the core yarns
- Acid or Caustic burns
- Broken or damaged core yarns
- Melting
- Melting partner
- Discoloration and stiff or brittle areas may mean chemical or ultraviolet damage has occurred
- Any fitting that is damaged, pitted, gouged, bent, twisted, or broken
- Any fitting that is damaged, pitted, gouged, bent, twisted, or broken
- Missing or illegible sling identification tag(s)

If you have any questions, please contact your Safety Manager.

Chain Slings

Chain slings should be purchased from the United States or Canada only. Grade 100 chains can be used for lifting, but rigging should not be used for lifting with alternative rigging in the USA.

Hardware

Rigging hardware devices are too numerous to mention. Some of the most common are shackles, eye bolts, hooks, master links, and turnbuckles. Regulations regarding hardware can be found in the ANSI/ASME B30.26 - Rigging Hardware and B30.10 - Hooks.

It is important that the proper hardware is selected and inspected before use in rigging a load. Each item must have the WLL displayed. The Company requires all hardware to be purchased in the United States or Canada from reputable sources. Hardware that is not identified. Hardware suspected to not pass inspection should not be used.

Inspection

Hardware is to be inspected each day before use by a Competent Person. If the hardware does not pass the inspection, it is to be taken out of service immediately. Do not use sufficient rigging. If the rigging hardware is not identified, it must be removed from service. It must be destroyed and documented. Do not allow employee owners to remove defective or deformed rigging from the job for their personal use.

Some hardware is known to wear, so not good. Rigging hardware can hide cracks and can make it difficult to detect deficiencies. All new hardware should be inspected before it is used.

Some replacement criteria for hardware include:

- Cracks in the hardware
- Removal by signs of any significant alteration of the hardware
- More than 15 % wear in critical areas such as saw or thread of hooks or other critical areas of hardware
- Signs of any heat damage to the hardware
- Remove from service if cracks, holes, or gouges are detected
- Remove from service if the hardware has been modified or altered in any way
- Evidence of heating or bending or welding
- Remove if the hardware does not function properly
- Any bent or twisted part
- Any part that is cracked or broken
- The serial claim tool will work

WIRE ROPE SLINGS

Wire rope slips are used for making an eye or attaching two pieces of wire rope together. Unlike wire rope and rigging assemblies, wire rope slips are to be used only where wire rope is terminated in a wedge socket. Wire rope slips have a guidelines when using wire rope slips and wedge sockets.

Wire rope slips can not be used to make slings used for lifting.

Wire rope slips can be used for grip wire or temporary hardware or for extra slack in regimented full protective systems.

Shackles

Shackles are used to connect rigging components. Shackles are made in many different shapes and sizes. Shackles are rated by the size of the material used to make the shackle and the width of the opening. The shackle must be rated for the load that is to be lifted. Shackles are made of forged steel and are available in different strengths. Shackles are rated by the size of the material used to make the shackle and the width of the opening. The shackle must be rated for the load that is to be lifted.

Round pin shackles should not be used for rigging. These shackles have a smooth pin that is secured only with a cotter key. Because of the lack of a secure pin, the shackle wires sides on the strength of the bow to resist opening of the pin location. These shackles may be used only for straight pull with one sling on the bow pulling 90 degrees to the pin.

Screw pin shackles are the most common shackles used in the rigging industry. They are easy to use and can be used in many different types of rigging. The pin has a shoulder that when properly tightened, secures the pin and helps the bow resist spreading under load. Screw pin shackles are available in many sizes. They are available in standard and chain shackles.

The shackle can be used onboard to the bow if necessary for grip security. The shackle should be screwed into the bow until the shoulder of the pin contacts the bow. Then back the pin out one turn so the eye and bow are centered from the shackle after the lift is completed. It is recommended by the manufacturers that the pin be secured with a cotter pin or wire to prevent the pin from backing out in field position. This will ensure the security of the pin and also strengthen the bow as discussed earlier.

Bolt type shackles are the most common. Bolt nut round pin shackles (smooth bores) but use a bolt type pin. The pin is threaded on the end to receive a nut and a cotter key. The pin may be inserted from either side of the shackle. A cotter key is inserted to keep the nut from working loose. Bolt type shackles are available in many sizes and are used in many types of rigging. It is important to remember that since the pin is sent in the eyes when the nut and cotter pin are removed, rotation may affect pin and eye capacity.

This shackle can be used anywhere the screw pin shackle can be used. It is recommended that the pin be secured with a cotter pin or wire when making permanent lines a screw. This is because of the security of the pin.

Bow

Shackle sizes are wide ranging. Using a shackle on a shorter hitch will result in a grip pressure. The D or bow between the shackle and sling can be increased and the sling will not wear as much. Shackles are rated for in line pull. Shackles should not be used when using a shackle from a shorter hitch the pin goes through the eye of the sling. This keeps the pin from unscrewing when the body of the sling is pulled.

Never Use Screw Pin to be Rotated In Sling Action

Never Side Load A Round Pin Shackle

ANGLE OF INCLUDE	LOSS OF WLL
NORMAL INCLINE	NONE
90°	30% LOSS
120°	50° LOSS

Sling stacking

Shackles are not designed to be used when sling angles are less than 30 degrees. When sling stranders for lifting, the shackles should be connected to the lifting device so that the load is applied to the crown. This ensures that stresses in the sling in the crown are to be capable of lifting the weight of the load. In this example, because the load is applied to the crown, the sling will not be overstressed. The shackle on the way is used for the sling should be of sufficient to large enough to accommodate the slings without stacking. It is also important that the shackle pin be large enough to allow the eyes when hooking prevented from a screw. This is because of the security of the pin.

EXHIBIT 2-3.1(A)
Correct Shackle Sizing Examples

HOOKS

EXHIBIT 2-3.2(A)
Hook Types

Eye hooks are a very common type of hook. There are many variations of the eye hook used in the rigging as well as on some load blocks and headache balls. When used on slings make sure the slings have thimbles in the eyes to increase the 3 to 4 ratio between the eye of the hook and the eye of the sling. Using shackles through the eye is an acceptable practice making this a versatile device.

Swivel hooks allow the hook to turn independently from the eye. These hooks can be used anywhere but are found on blocks and balls or other lifting devices where the limited turning of the hook occurs.

Shank hooks are used primarily in load blocks. These hooks range from one ton to 300 ton capacity for large hooks. Duplex hooks range in size from 25 tons to 600 tons. The shank of the hook can be machined for bearings and threaded for installation in a load block.

Hooks, because of their construction rely solely on the strength of the material for bending resistance. There are no pins or bolts to help the hook keep its shape.

Tip loading, side loading, or excessively low sling angles can cause the hook to deform. Usually, when a hook is deformed, the first thing noticed is the safety latch does not function properly. If the safety latch is not damaged but does not function properly, you should suspect the hook is deformed or damaged. Sling angle in hooks is critical to safety. Sling angles below 45 degrees are not permitted in a hook. When low sling angles are used, the hook can be deformed. Also when low sling angles are used, it is possible that a sling could ride up the tip and come off the hook. The safety latch will prevent unloaded slings from coming off the hook but loaded slings will go through the latch.

EXHIBIT 2-3.2(B)
Hook Sling Angle
Sling angles must be at least 45 degrees. Sling angles below 45 degrees are not permitted in the hook.

Inspection

The inspection criterion for a hook is the same as for other hardware. Deformation of the hook is a primary concern however; nicks, gouges, and wear are also causes for replacement.

Critical areas are shaded. No more than 5% wear is allowed in the red area. No more than 10% in grey areas. Wear on the tip of the hook is not critical to the strength of the hook.

EXHIBIT 2-3.2(C)
Hook Inspection and Out-Of-Service Criteria

MASTER LINKS (O-RINGS)

Master links are for the most part an underutilized rigging device. The most common use of the master link is to collect the slings in multi-leg sling assemblies. The master link comes in many shapes and sizes. The oval, round, and pear shapes can be used in many applications where size matters.

EXHIBIT 2-3.3
Master Link Shapes

The master link can be used on large hooks in place of large shackles. For example, you might use a 55-ton shackle because it will fit the hook of the load block on the crane. The 55-ton shackle weight is 86 pounds. A comparable capacity master link weighs about 37 pounds and dimensionally will easily fit the same hook. Usually, when a large shackle is used on a hook it is selected for the dimensions and not the capacity.

EYE BOLTS

Eye bolts are often used to provide attachment points for rigging.

EXHIBIT 2-3.4
Eye Bolt Types
There are three basic types of eye bolts.

When lifting with Eye Bolts

- Only eye bolts with WLL should be used. Basic eye bolts bought at store do not meet lifting criteria.
- Always lift the load with a steady, even pull - do not jerk.
- Always apply a load to the eye in the plane of the eye - not an angle.
- If lifting at an angle, the capacity of the eye bolt must be reduced.
- Only eye bolts with shoulders can be pulled at an angle.

EXHIBIT 2-3.4
Lifting at an Angle
The capacity of the eye bolt is reduced when lifting at an angle

DIRECTION OF PULL (IN DEG)	ADJUSTED WORKING LOAD LIMIT
45°	30% OF RATED W.L.L.
90°	25% OF RATED W.L.L.

EXHIBIT 2-3.4(B)
Hex Nut Positioning

TURNBUCKLES

Turnbuckles are used for positioning. Turnbuckles can be used in line or straight pull only. If used where vibration is a concern, use either a lock nut to lock the body to the bolt or mouse the body to the end fitting. Turnbuckle capacities are available in the manufacturer's catalog. Be sure the end fittings match the drawings in the catalog as this is typically the limited factor for capacity. For instance, a turnbuckle with a hook and hook configuration has less capacity than an equal size and stroke turnbuckle with an eye and eye configuration.

EXHIBIT 2-3.5(B)
Types of Turnbuckles

SPREADER BAR/LIFTING BEAMS

Spreader bars and lifting beams are regulated by ANSI B30.20 Under the Hook Lifting Devices. Spreader bars are used to lift long hard to handle loads. The spreader bar can allow slings to lift in a vertical position reducing or eliminating the effects of the rigging triangle. This is very important for loads that have limited structural capacities and where bending or damage could occur if rigged with sling angles. Typically the spreader bar uses attachment points located on the ends of the beam. Above the bar, the rigging usually forms a triangle. Below the bar, the slings can be vertical or at an angle.

EXHIBIT 2-3.6(A)
Spreader Bar

Lifting beams are used for the same reason as a spreader bar. Lifting beams have several attachment point options for attaching the beam to the load. Lifting beams may have one or more attachment points for attaching the beam to the crane. These characteristics make the lifting beam a versatile lifting device.

EXHIBIT 2-3.6(B)
Lifting Bar

Equalizers are much the same as lifting beams. Equalizers are used to equalize that each sling lifts below the bar. The equalizer can be used in either position. When an equalizer is used by a single crane, the crane attaches to the single pad eye on the beam and the load is attached to the dual pad eyes on the bottom. This allows the beam to equalize the loading on the bottom pad eyes.

For two crane lifts the equalizer is inverted and the cranes attach to the bar on the dual pad eye side. The load is attached to the single pad eye ensuring that each crane lifts only half the load.

For an equalizer to work properly, the dual pad eyes must be the same dimension as the single pad eye.

EXHIBIT 2-3.6(C)
Equalizer

EXHIBIT 2-3.6(D)
Dual Crane Position

Another form of an equalizer is the triangle plate. The triangle plate uses the same concept as the equalizer bar and can be used in either position. Since not all slings are exactly the same length, a triangle plate can ensure that each sling is equally loaded by pivoting to equalize the loading when lifted.

For equalizer to be effective, only one sling should be used at each eye location. They are most effective when more than three slings are used in a lift.

In all cases, lifting beams, spreader bars and equalizers must be designed by a qualified engineer, built by a qualified fabricator and load tested.

The load rating for a device should not be more than 80% of the maximum load sustained during the load test. Test loads shall not be more than 125% of the rated capacity unless otherwise recommended by the manufacturer.

Marking Identification

All lifting bars and beams must have identification on the bar. The following is required:

- Manufacturer's name and address
- Serial Number
- Weight if over 100 pounds
- Rated Load (capacity)
- ASME BTH-1 Design Class
- ASME BTH-1 Service Class

Warning labels for the operation of the device will be in place as well. Warn the operator of the dangers of overload, using damaged devices, lifting suspended loads over other people, etc.

Inspection

On all new lifting bars and beams, an initial inspection should be performed to verify that compliance with all applicable provisions of ANSI B30.20.

There are three basic intervals for inspection.

01 Every lift inspection
02 Frequent inspection
03 Periodic inspections

All "job-made lifting devices" must meet the design and testing requirements of ANSI B30.20. The documentation must be readily available upon request. Copies should also be on file in the Safety Department.

General Rigging Inspection

Inspection of rigging is a key element of a safe lift. All inspection criteria set forth by manufacturers or other regulatory agencies are the minimum requirements for rigging devices. If a rigging device exceeds any criteria, the WLL of the device is not valid. Daily inspections of rigging devices prior to use are a core responsibility of the rigger.

RIGGING TRIANGLE

Understanding the rigging triangle and how it affects the loads in rigging is a vital yet often ignored or misunderstood part of the rigger's responsibilities. Attaching more than one sling to a load and forming a triangle with the slings causes the weight of the load to be multiplied. The mechanical forces induced into the slings must be accounted for the same as the load when sizing rigging.

There are three basic factors that affect the load on each leg of the rigging.

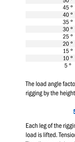
01 Weight of the load - The weight of the load is the most important factor regarding lifting operations. It is vital that the weight of the load is known as close as possible to any hoisting of the load. Whatever method is used for determining the weight, must be accurate.

02 Center of Gravity - The location of the center of gravity (COG) in relation to the lifting points must be known before the share of the load can be determined. The share of the load is the amount of weight of the given object each leg of the rigging will lift. For example, a load has two attachment points and weighs 1,000 pounds. The attachment points are equally spaced from the COG. Each leg will lift 500 pounds.

If a load is non-symmetrical and the center of gravity is located closer to one attachment point than another, the leg attached closer to the COG will lift more weight than the other leg.

03 Angle (3) of the slings - Finally the angle of the slings will have a profound effect on the tension in each leg. The tension can be easily calculated by dividing the length of the rigging by the height of the rigging. The answer is known as the Load Angle Factor.

EXHIBIT 3.0.021
Load Angle Factor



In the above examples, the weight of the load is 1,000.
Each attachment point is equally spaced (48") around the COG. The rigging length is 96" and the rigging height is 83".

Since the load is rigged equally around the COG, each leg will lift an equal share of the load of 500 pounds.

EXHIBIT 3.0.022
This chart represents the different load angle factor associated with the sling angle in the above example.

SLING ANGLE	LOAD ANGLE FACTOR
90 °	1.000
85 °	1.004
80 °	1.015
75 °	1.035
70 °	1.064
65 °	1.104
60 °	1.155
55 °	1.221
50 °	1.305
45 °	1.414
40 °	1.555
35 °	1.742
30 °	2.000
25 °	2.364
20 °	2.924
15 °	3.861
10 °	5.747
5 °	11.490

The load angle factor is determined by dividing the length of the rigging by the height.

96" / 83" = 1.157
500 lbs. x 1.157 = 578.5 lbs.

Each leg of the rigging will feel 578.5 pounds of tension when the load is lifted. Tension must be accounted for the same as weight. The slings and the shackles attached to the load must have a WLL sufficient to lift 578.5 pounds. The shackle at the top of the triangle must have a WLL to lift 1,000 pounds. The additional tension in the slings does not affect the top shackle.

If the object to be hoisted is non-symmetrical, it is more difficult to calculate the tension in the slings. The load angle factor is still a simple calculation but the share of the load is more difficult. In the example below, the COG is closer to one lifting point than the other. The share of the load can be calculated as below.

The distance from the center of gravity to the opposite lifting point, divided by the overall distance between the lifting points, times the weight of the load.

EXHIBIT 3.0.023
Share of the Load Calculation Example

Vertical Force on Sling B:
104" / 144" = .722 or 72%
5 tons x 72% = 3.6 tons

Vertical Force on Sling A:
40" / 144" = .277 or 28%
5 tons x 28% = 1.4 tons

Since sling B is attached closer to the COG than sling A, sling B will have more load than A. The load angle factor for sling A is 2, and the load angle factor for sling B is 1.2. Again, the load angle factor is length divided by height.

To calculate the tension in the slings, apply the load angle factor to the share of the load as follows:

Sling A
1.4 tons x 2 = 2.8 tons

Sling B
3.6 tons x 1.2 = 4.32 tons

RIGGING HITCHES

There are three basic rigging hitches.

01 Straight
02 Choke
03 Basket

Straight Hitch

A straight hitch is any hitch where the pull or tension is applied directly in line from one point to another and the sling is not wrapped around the load.

EXHIBIT 3.0.024
Straight Hitch

STRAIGHT

Choke Hitch

The choke hitch is the most versatile and widely used hitch. A choke hitch can be used when there isn't an attachment point on the load. The sling can be wrapped around the load and run back through an eye to secure the sling to the load. The choking action of the sling on the load helps keep the sling in place without slipping.

However, when lifting a load with only one sling in the choke hitch, the load can slide out and drop. Another thing to be aware of is when a choke hitch is used, the sling will lose about 25% of its straight hitch capacity. Further, if the hitch is tightened, more capacity is lost due to the mechanical forces input to the slings.

EXHIBIT 3.0.025
Choke Hitch

CHOKE

Basket Hitch

The basket hitch is likely the least used hitch. In many cases, the basket hitch provides the least amount of load control. If the basket is not secured on the load, it will likely move when the load is lifted.

Under certain conditions, basket hitches can double a sling's capacity. For that to happen, the sling must be wrapped around an object twenty times the diameter of the sling and the legs must be vertical.

EXHIBIT 3.0.026
Basket Hitch

BASKET

CENTER OF GRAVITY

Finding the center of gravity (COG) can be difficult. For symmetrical shapes, the COG will be located relative to the middle of the object. For non-symmetrical shapes, the COG will likely be located away from the middle of the object.

Exhibit 3.0.027
Example of finding the COG on a non-symmetrical solid object

20,000 lbs. + 10,000 lbs. = 30,000 lbs.
20,000 lbs. / 30,000 lbs. = 66.6%
15' x 66.6% = 9.99'

Knowing where the COG is located is important for the sizing of the rigging. It is also important because when a load is lifted, the COG will come directly below the hook of the crane. If the load is not initially rigged with the hook over the COG, the load will swing when hoisted which could cause damage to the crane, other equipment, ground personnel, or the structure being constructed.

Many times the COG will be marked on an object by the manufacturer. If it is not marked, it is possible to calculate the location. There are several methods of finding the COG. Refer to Bob's Rigging and Crane Handbook for methods of determining the location of the COG.

If the object is solid, the COG can be calculated using the following method. Break the object down into simple shapes and calculate the mass and weight of each object.

If the object is not solid, it may be necessary to perform trial lifts to determine the COG. For trial lift, the weight of the object must be known. The rigging used should be capable of supporting the entire weight of the load. This will ensure that the rigging is adequate for the trial lift.

One method of trial lifting is as follows.

Lift at point A and record the weight (VERT A).
Lift at point B and record the weight (VERT B).

Make sure the object is supported on the end for accuracy.

Distance (D) from Point A to Point B is D=10 feet

COG from point A = $\frac{\text{VERT B}}{(\text{VERT A} + \text{VERT B})}$ x D

VERT A = 500 lbs.
VERT B = 1,500 lbs.

$\frac{1,500}{(500 + 1,500)}$ x 10 = 7.5 feet

Trial Lifting Method #1

Another method of test lifting is as follows.

The weight of the lift must be known. Each sling and rigging device should have enough capacity to lift the entire weight of the load.

With equal length slings, lift the object clear of the ground. Use a plumb bob from the hook of the crane down to the load. Mark a vertical line on the object.

Set the load down and install a longer sling on the end that was highest during the previous test lift. Lift the object again and mark a vertical line on the object. The point where the two lines intersect is the center of gravity of the object.
